

Dual 50MHz, Low Noise, Rail-to-Rail, CMOS Op Amp

FEATURES

Input Bias Current: 1pA (Typ at 25°C)
 Low Offset Voltage: 100µV Max

Low Offset Drift: 2.5μV/°C Max
 0.1Hz to 10Hz Noise: 1.5μV_{P-P}

■ Slew Rate: 40V/µs

Gain Bandwidth Product: 50MHzOutput Swings Rail-to-Rail

Supply Operation:2.8V to 6V LTC62442.8V to ±5.25V LTC6244HV

Low Input Capacitance: 2.1pF

Available in 8-Pin MSOP and Tiny DFN Packages

APPLICATIONS

- Photodiode Amplifiers
- Charge Coupled Amplifiers
- Low Noise Signal Processing
- Active Filters
- Medical Instrumentation
- High Impedance Transducer Amplifier

DESCRIPTION

The LTC®6244 is a dual high speed, unity-gain stable CMOS op amp that features a 50MHz gain bandwidth, 40V/µs slew rate, 1pA of input bias current, low input capacitance and rail-to-rail output swing. The 0.1Hz to 10Hz noise is just $1.5\mu V_{P-P}$ and 1kHz noise is guaranteed to be less than $12nV/\sqrt{Hz}$. This excellent AC and noise performance is combined with wide supply range operation, a maximum offset voltage of just $100\mu V$ and drift of only $2.5\mu V/^{\circ}C$, making it suitable for use in many fast signal processing applications, such as photodiode amplifiers.

This op amp has an output stage that swings within 35mV of either supply rail to maximize the signal dynamic range in low supply applications. The input common mode range extends to the negative supply. It is fully specified on 3V and 5V, and an HV version guarantees operation on supplies of ±5V.

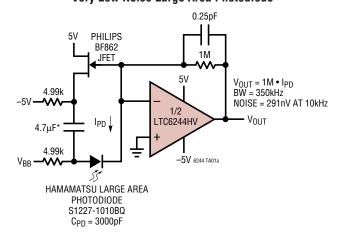

The LTC6244 is available in the 8-pin MSOP, and for compact designs, it is packaged in the tiny dual fine pitch lead free (DFN) package.

 $\frac{47}{47}$, LT, LTC and LTM are registered trademarks of Linear Technology Corporation. All other trademarks are the property of their respective owners.

Note 1: Stresses beyond those listed under Absolute Maximum Ratings may cause permanent damage to the device. Exposure to any Absolute Maximum Rating condition for extended periods may affect device reliability and lifetime.

Note 2: A heat sink may be required to keep the junction temperature below the absolute maximum rating when the output is shorted indefinitely.

Note 3: The LTC6244C/LTC6244HVC are guaranteed to meet specified performance from 0°C to 70°C. They are designed, characterized and expected to meet specified performance from -40°C to 85°C, but are not tested or QA sampled at these temperatures. The LTC6244I/LTC6244HVI, are guaranteed to meet specified performance from -40°C to 85°C. The LTC6244H is guaranteed to meet specified performance from -40°C to 125°C.

Note 4: ESD (Electrostatic Discharge) sensitive device. ESD protection devices are used extensively internal to the LTC6244; however, high electrostatic discharge can damage or degrade the device. Use proper ESD handling precautions.

Note 5: Matching parameters are the difference between the two amplifiers of the LTC6244. CMRR and PSRR match are defined as follows: CMRR and PSRR are measured in μ V/V on the amplifiers. The difference is calculated between the sides in μ V/V. The result is converted to dB.

www.DataSheet4U.com

Note 6: This parameter is not 100% tested.

Note 7: This specification is limited by high speed automated test capability. See Typical Characteristics curves for actual typical performance.

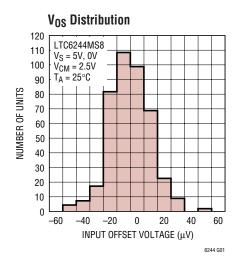

Note 8: Current noise is calculated from the formula: $i_n = (2ql_B)^{1/2}$ where $q = 1.6 \times 10^{-19}$ coulomb. The noise of source resistors up to $50G\Omega$ dominates the contribution of current noise. See also Typical Characteristics curve Noise Current vs Frequency.

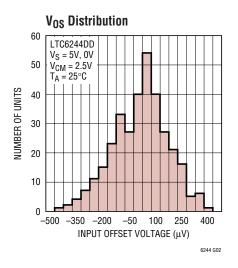

Note 9: Output voltage swings are measured between the output and power supply rails.

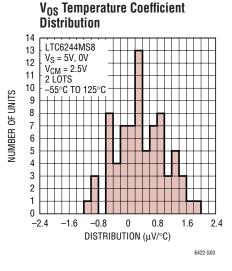

Note 10: Minimum supply voltage is guaranteed by the power supply rejection ratio test.

Note 11: Slew rate is measured in a gain of -2 with $R_F=1k$ and $R_G=500\Omega$. V_{IN} is $\pm 1V$ and V_{OUT} slew rate is measured between -1V and $\pm 1V$. On the LTC6244HV/LTC6245HV, V_{IN} is $\pm 2V$ and V_{OUT} slew rate is measured between -2V and $\pm 2V$.

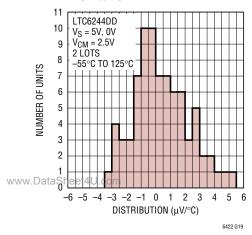

Note 12: Full-power bandwidth is calculated from the slew rate: FPBW = $SR/2\pi V_P$.

Amplifier Characteristics

Figure 1 is a simplified schematic of the LTC6244, which has a pair of low noise input transistors M1 and M2. A simple folded cascode Q1, Q2 and R1, R2 allow the input stage to swing to the negative rail, while performing level shift to the Differential Drive Generator. Low offset voltage is accomplished by laser trimming the input stage.

Capacitor C1 reduces the unity cross frequency and improves the frequency stability without degrading the gain bandwidth of the amplifier. Capacitor C_M sets the overall amplifier gain bandwidth. The differential drive generator supplies signals to transistors M3 and M4 that swing the output from rail-to-rail.

The photo of Figure 2 shows the output response to an input overdrive with the amplifier connected as a voltage follower. If the negative going input signal is less than a diode drop below V^- , no phase inversion occurs. For input signals greater than a diode drop below V^- , limit the current to 3mA with a series resistor R_S to avoid phase inversion.

The input common mode voltage range extends from V^- to $V^+ - 1.5V$. In unity gain voltage follower applications, exceeding this range by applying a signal that reaches 1V from the positive supply rail can create a low level instability at the output. Loading the amplifier with several hundred which compares will reduce or eliminate the instability.

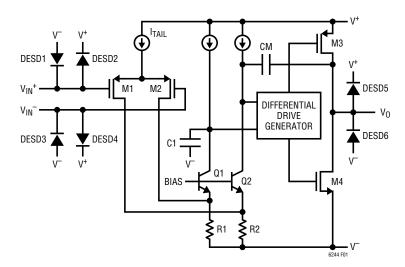

Figure 1. Simplified Schematic

ESD

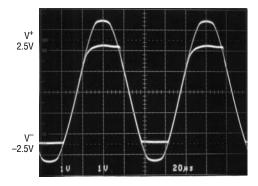

The LTC6244 has reverse-biased ESD protection diodes on all input and outputs as shown in Figure 1. These diodes protect the amplifier for ESD strikes to 4kV. If these pins are forced beyond either supply, unlimited current will flow through these diodes. If the current transient is less than 1 second and limited to one hundred milliamps or less, no damage to the device will occur.

The amplifier input bias current is the leakage current of these ESD diodes. This leakage is a function of the temperature and common mode voltage of the amplifier, as shown in the Typical Performance Chacteristics.

Noise

The LTC6244 exhibits low 1/f noise in the 0.1Hz to 10Hz region. This $1.5\mu V_{P-P}$ noise allows these op amps to be used in a wide variety of high impedance low frequency applications, where Zero-Drift amplifiers might be inappropriate due to their input sampling characteristic.

In the frequency region above 1kHz the LTC6244 also shows good noise voltage performance. In this frequency region, noise can easily be dominated by the total source

V_{OUT} AND V_{IN} OF FOLLOWER WITH LARGE INPUT OVERDRIVE

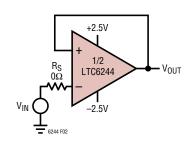

Figure 2. Unity Gain Follower Test Circuit

62441

resistance of the particular application. Specifically, these amplifiers exhibit the noise of a 4k resistor, meaning it is desirable to keep the source and feedback resistance at or below this value, i.e., $R_S + R_G || R_{FB} \le 4k$. Above this total source impedance, the noise voltage is not dominated by the amplifier.

Noise current can be estimated from the expression $i_n = \sqrt{2qI_B}$, where $q = 1.6 \cdot 10^{-19}$ coulombs. Equating $\sqrt{4kTR}\Delta f$ and $R_S\sqrt{2qI_B}\Delta f$ shows that for source resistors below $50G\Omega$ the amplifier noise is dominated by the source resistance. See the Typical Characteristics curve Noise Current vs Frequency.

Proprietary design techniques are used to obtain simultaneous low 1/f noise and low input capacitance. Low input capacitance is important when the amplifier is used with high source and feedback resistors. High frequency noise from the amplifier tail current source, I_{TAIL} in Figure 1, couples through the input capacitance and appears across these large source and feedback resistors.

Stability

The good noise performance of these op amps can be attributed to large input devices in the differential pair. Above several hundred kilohertz, the input capacitance can cause amplifier stability problems if left unchecked.

When the feedback around the op amp is resistive (R_F), a pole will be created with R_F, the source resistance, source capacitance (R_S, C_S), and the amplifier input capacitance.

In low gain configurations and with R_F and R_S in even the kilohm range (Figure 3), this pole can create excess phase shift and possibly oscillation. A small capacitor C_F in parallel with R_F eliminates this problem.

Achieving Low Input Bias Current

The DD package is leadless and makes contact to the PCB beneath the package. Solder flux used during the attachment of the part to the PCB can create leakage current paths and can degrade the input bias current performance of the part. All inputs are susceptible because the backside paddle is connected to V⁻ internally. As the input voltage changes or if V⁻ changes, a leakage path can be formed and alter the observed input bias current. For lowest bias current, use the LTC6244 in the MS8 package.

Photodiode Amplifiers

Photodiodes can be broken into two categories: large area photodiodes with their attendant high capacitance (30pF to 3000pF) and smaller area photodiodes with relatively low capacitance (10pF or less). For optimal signal-to-noise performance, a transimpedance amplifier consisting of an inverting op amp and a feedback resistor is most commonly used to convert the photodiode current into voltage. In low noise amplifier design, large area photodiode amplifiers require more attention to reducing op amp input voltage noise, while small area photodiode amplifiers require more attention to reducing op amp input current noise and parasitic capacitances.

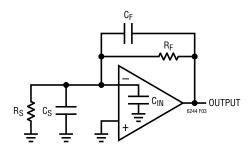

Figure 3. Compensating Input Capacitance

Large Area Photodiode Amplifiers

A simple large area photodiode amplifier is shown in Figure 4a. The capacitance of the photodiode is 3650pF (nominally 3000pF), and this has a significant effect on the noise performance of the circuit. For example, the photodiode capacitance at 10kHz equates to an impedance of $4.36k\Omega$, so the op amp circuit with $1M\Omega$ feedback has a noise gain of NG = 1 + 1M/4.36k = 230 at that frequency. Therefore, the LTC6244 input voltage noise gets to the output as $NG \bullet 7.8nV/\sqrt{Hz} = 1800nV/\sqrt{Hz}$, and this can clearly be seen in the circuit's output noise spectrum in Figure 4b. Note that we have not yet accounted for the op amp current noise, or for the $130nV/\sqrt{Hz}$ of the gain resistor, but these are obviously trivial compared to the op

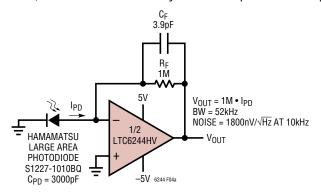

Figure 4a. Large Area Photodiode Transimpedance Amplifier

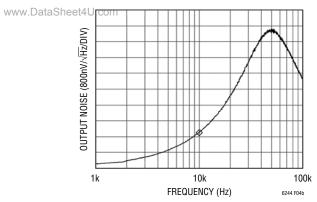

Figure 4b. Output Noise Spectral Density of the Circuit of Figure 4a. At 10kHz, the 1800nV/ $\sqrt{\text{Hz}}$ Output Noise is Due Almost Entirely to the 7.8nV Voltage Noise of the LTC6244 and the High Noise Gain of the 1M Feedback Resistor Looking Into the High Photodiode Capacitance

amp voltage noise and the noise gain. For reference, the DC output offset of this circuit is about $100\mu V$, bandwidth is 52kHz, and the total noise was measured at $1.7mV_{RMS}$ on a 100kHz measurement bandwidth.

An improvement to this circuit is shown in Figure 5a, where the large diode capacitance is bootstrapped by a 1nV/√Hz JFET. This depletion JFET has a V_{GS} of about -0.5V, so that R_{BIAS} forces it to operate at just over 1mA of drain current. Connected as shown, the photodiode has a reverse bias of one V_{GS}, so its capacitance will be slightly lower than in the previous case (measured 2640pF), but the most drastic effects are due to the bootstrapping. Figure 5b shows the output noise of the new circuit. Noise at 10kHz is now 220nV/ $\sqrt{\text{Hz}}$, and the 130nV/ $\sqrt{\text{Hz}}$ noise thermal noise floor of the 1M feedback resistor is discernible at low frequencies. What has happened is that the $7.8 \text{nV}/\sqrt{\text{Hz}}$ of the op amp has been effectively replaced by the $1nV/\sqrt{Hz}$ of the JFET. This is because the 1M feedback resistor is no longer "looking back" into the large photodiode capacitance. It is instead looking back into a JFET gate capacitance, an op amp input capacitance. and some parasitics, approximately 10pF total. The large photodiode capacitance is across the gate-source voltage of the low noise JFET. Doing a sample calculation at 10kHz as before, the photodiode capacitance looks like $6k\Omega$, so the $1nV/\sqrt{Hz}$ of the JFET creates a current noise of $1nV/6k = 167fA/\sqrt{Hz}$. This current noise necessarily flows through the 1M feedback resistor, and so appears as $167 \text{ nV}/\sqrt{\text{Hz}}$ at the output. Adding the $130 \text{ nV}/\sqrt{\text{Hz}}$ of the resistor (RMS wise) gives a total calculated noise density of $210 \text{nV}/\sqrt{\text{Hz}}$, agreeing well with the measured noise of Figure 5b. Another drastic improvement is in bandwidth, now over 350kHz, as the bootstrap enabled a reduction of the compensating feedback capacitance. Note that the bootstrap does not affect the DC accuracy of the amplifier. except by adding a few picoamps of gate current.

There is one drawback to this circuit. Most photodiode circuits require the ability to set the amount of applied reverse bias, whether it's 0V, 5V, or 200V. This circuit has a fixed reverse bias of about 0.5V, dictated by the JFET.

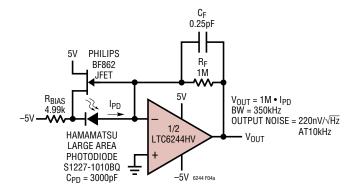

Figure 5a. Large Area Diode Bootstrapping

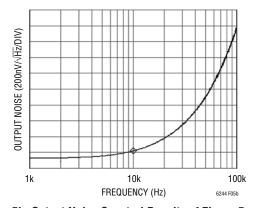

Figure 5b: Output Noise Spectral Density of Figure 5a. The Simple JFET Bootstrap Improves Noise (and Bandwidth)
Drastically. Noise Density at 10kHz is Now 220nV/√Hz, About a 8.2x Reduction. This is Mostly Due to the Bootstrap Effect of Swapping the 1nV/√Hz of the JFET for the 7.8nV/√Hz of the
www.□OppAmpt4∪.com

The solution is as shown in the circuit of Figure 6a, which uses a capacitor-resistor pair to enable the AC benefits of bootstrapping while allowing a different reverse DC voltage on the photodiode. The JFET is still running at the same current, but an arbitrary reverse bias may be applied to the photodiode. The output noise spectrum of the circuit with 0V of photodiode reverse bias is shown in Figure 6b. Photodiode capacitance is again 3650pF, as in the original circuit of Figure 4a. This noise plot with 0V bias shows that bootstrapping alone was responsible for a factor of 6.2 noise reduction, from $1800\text{nV}/\sqrt{\text{Hz}}$ to $291\text{nV}/\sqrt{\text{Hz}}$ at 10kHz, independent of photodiode capacitance. However, photodiode capacitance can now can be reduced arbitrarily

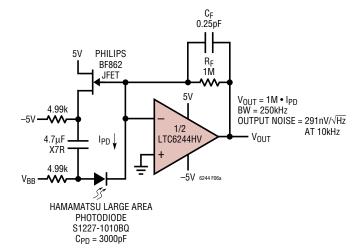

Figure 6a. The Addition of a Capacitor and Resistor Enable the Benefit of Bootstrapping While Applying Arbitrary Photodiode Bias Voltage V_{BB}

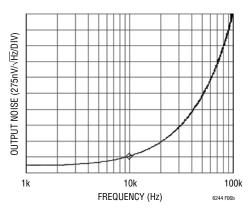

Figure 6b: Output Spectrum of Circuit of Figure 6a, with Photodiode Bias at 0V. Photodiode Capacitance is Back Up, as in the Original Circuit of Figure 4a. However, it can be Reduced Arbitrarily by Providing Reverse Bias. This Plot Shows that Bootstrapping Alone Reduced the 10kHz Noise Density by a Factor of 6.2, from $1800nV/\sqrt{Hz}$ to $291nV/\sqrt{Hz}$.

by providing reverse bias, and the photodiode can also be reversed to support either cathode or anode connections for positive or negative going outputs.

The circuit on the last page of this data sheet shows further reduction in noise by paralleling four JFETs to attain $152\text{nV}/\sqrt{\text{Hz}}$ at 10kHz, a noise of 12 times less than the basic photodiode circuit of Figure 4a.

Small Area Photodiode Amplifiers

Small area photodiodes have very low capacitance, typically under 10pF and some even below 1pF. Their low capacitance makes them more approximate current sources to higher frequencies than large area photodiodes. One of the challenges of small area photodiode amplifier design is to maintain low input capacitance so that voltage noise does not become an issue and current noise dominates. A simple small area photodiode amplifier using the LTC6244 is shown in Figure 7. The input capacitance of the amplifier consists of C_{DM} and one C_{CM} (because the +input is

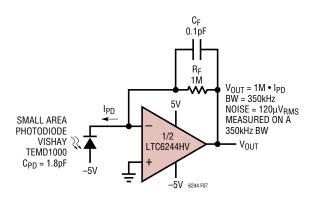

Figure 7. LTC6244 in a Normal TIA Configuration

grounded), or about 6pF total. The small photodiode has 1.8pF, so the input capacitance of the amplifier is dominating the capacitance. The small feedback capacitor is an actual component (AVX Accu-F series), but it is also in parallel with the op amp lead, resistor and parasitic capacitances, so the total real feedback capacitance is probably about 0.4pF. The reason this is important is that this sets the compensation of the circuit and, with op amp gain bandwidth, the circuit bandwidth. The circuit as shown has a bandwidth of 350kHz, with an output noise of $120\mu V_{RMS}$ measured over that bandwidth.

The circuit of Figure 8a makes some slight improvements. Operation is still transimpedance mode, with R_F setting the gain to $1M\Omega$. However, a noninverting input stage A1 with a gain of 3 has been inserted, followed by the usual inverting stage performed by A2. Note what this achieves. The amplifier input capacitance is bootstrapped by the feedback of R2:R1, eliminating the effect of A1's input C_{DM} (3.5pF), and leaving only one C_{CM} (2.1pF). The op amp at Pins 5, 6 and 7 was chosen for the input amplifier to eliminate extra pin-to-pin capacitance on the (+) input. The lead capacitance on the corner of an MSOP package is only about 0.15pF. By using this noninverting configuration, input capacitance is minimized.

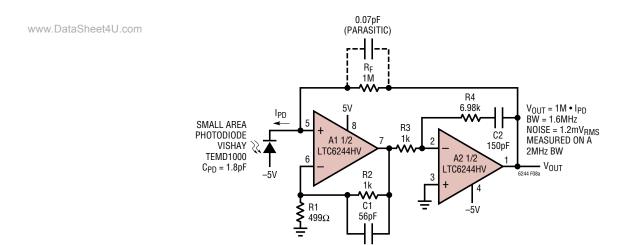

Figure 8a: Using Both Op Amps for Higher Bandwidth. A1 Provides a Gain of 3 Within the Loop, Increasing the Gain Bandwidth Product. This Bootstraps the C_{DM} Accross A1's Inputs, Reducing Amplifier Input Capacitance. Inversion is Provided by A2, so that the Photodiode Looks Into a Noninverting Input. Pin 5 was Selected Because it is in the Corner, Removing One Lead Capacitance

Total capacitance at the amplifier's input is now one C_{CM} (2.1pF) plus the photodiode capacitance C_{PD} (1.8pF), or about 4pF accounting for parasitics. The shunt impedance at 1MHz, for example, is $X_C = 1/(2\pi fC) = 39.8k\Omega$, and therefore, the noise gain at 1MHz is NG = $1+Rf/X_C = 26$. The input voltage noise of this amplifier is about $15 \text{ nV}/\sqrt{\text{Hz}}$, after accounting for the effects of R1 through R3, the noise of the second stage and the fact that voltage noise does rise with frequency. Multiplying the noise gain by the input voltage noise gives an output noise density due to voltage noise of 26 • $15 \text{nV}/\sqrt{\text{Hz}} = 390 \text{nV}/\sqrt{\text{Hz}}$. But the noise spectral density plot of Figure 8b shows an output noise of $782 \text{nV}/\sqrt{\text{Hz}}$ at 1MHz. The extra output noise is due to input current noise, multiplied by the feedback impedance. So while the circuit of Figure 8a does increase bandwidth, it does not offer a noise advantage. Note, however, that the 1.2mV_{RMS} of noise is now measured in a 2MHz bandwidth, instead of over a 350kHz bandwidth of the previous example.

A Low Noise Fully Differential Buffer/Amplifier

In differential signal conditioning circuits, there is often a need to monitor a differential source without loading or

adding appreciable noise to the circuit. In addition, adding gain to low level signals over appreciable bandwidth is extremely useful. A typical application for a low noise, high impedance, differential amplifier is in the baseband circuit of an RFID (radio frequency identification) receiver. The baseband signal of a UHF RFID receiver is typically a low level differential signal at the output of a demodulator with differential output impedance in the range of 100Ω to 400Ω . The bandwidth of this signal is 1MHz or less.

The circuit of Figure 9a uses an LTC6244 to make a low noise fully differential amplifier. The amplifier's gain, input impedance and –3dB bandwidth can be specified independently. Knowing the desired gain, input impedance and –3dB bandwidth, R_G , C_F and C_{IN} can be calculated from the equations shown in Figure 9b. The common mode gain of this amplifier is equal to one ($V_{OUTCM} = V_{INCM}$) and is independent of resistor matching. The component values in the Figure 9a circuit implement a 970kHz, gain = 5, differential amplifier with 4k input impedance. The output differential DC offset is typically less than $500\mu V$. The differential input referred noise voltage density is shown in Figure 10. The total input referred noise in a 1MHz bandwidth is $16\mu V_{RMS}$.

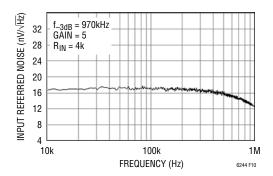

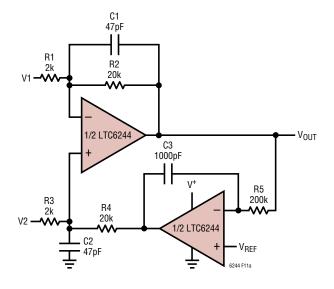

Figure 10. Differential Input Referred Noise

A Low Noise AC Difference Amplifier

In the signal conditioning of wideband sensors and transducers, a low noise amplifier is often used to provide gain for low level AC difference signals in the frequency range of a few Hertz to hundreds of kilo-Hertz. In addition, the amplifier must reject common mode AC signals and its input impedance should be higher than the differential source impedance. Typical applications are piezoelectric sensors used in sonar, sound and ultrasound systems and LVDT (linear variable differential transformers) for displacement measurements in process control and robotics.

The Figure 11a circuit is a low noise, single supply AC difference amplifier. The amplifier's low frequency -3dB bandwidth is set with resistor R5 and capacitor C3, while the upper -3dB bandwidth is set with R2 and C1. The input common mode DC voltage can vary from ground to V⁺ and the output DC voltage is equal to the V_{REF} voltage. The amplifier's gain is the ratio of resistors R2 to R1 (R4 = R2 and R3 = R1). The component values in the circuit of Figure 11a implement an 800Hz to 160kHz AC amplifier with a gain equal to 10 and $12nV/\sqrt{Hz}$ input referred voltage noise density shown in Figure 11b. The total input referred wideband noise is $4.5\mu V_{RMS}$, in the bandwidth of 500Hz to 200kHz.

$$\begin{split} &V_{OUT} = \text{GAIN} \bullet \left(\text{V2} - \text{V1} \right) + V_{REF} \\ &\text{GAIN} = \frac{\text{R2}}{\text{R1}} \; \text{R3} = \text{R1}, \; \text{R4} = \text{R2}, \; \text{C1} = \text{C2} \\ &\text{BANDWIDTH} = f_{HI} - f_{LO} \\ &f_{HI} = \frac{1}{2 \bullet \pi \bullet \text{R2} \bullet \text{C1}}, \; f_{LO} = \frac{1}{2 \bullet \pi \bullet \text{R5} \bullet \text{C3}} \end{split}$$
